Abstract

Once a program file is modified, the recompilation time should be minimized, without sacrificing execution speed or high level object oriented features. The recompilation time is often a problem for the large graphical interactive distributed applications tackled by modern OO languages. A compilation server and fast code generator were developed and integrated with the SRC Modula-3 compiler and Linux ELF dynamic linker. The resulting compilation and recompilation speedups are impressive. The impact of different language features, processor speed, and application size are discussed.

Keywords: Compiler, Code generator, Dependency analysis, Persistent cache, Smart recompilation

1 Introduction

Recompilation speed is only one ingredient in the global picture of programming productivity. Nonetheless, its impact on programmer satisfaction is not

to be underestimated. Interpreters are sometimes seen as the solution for zero recompilation time. However, the modified module needs to be parsed into bytecode, which is not too different from machine code, especially if the link editing phase is partially obviated by dynamic linking.

The recompilation may be divided into the following phases. The smart recompilation phase determines the modified files and computes the minimal set of files to recompile. The parsing and code generation phases convert the source code files into relocatable binary files. The prelink phase computes package wide information such as initialization order. Finally, the link phase combines all the relocatable binary files into a library or executable program.

These phases are detailed in section 2 along with a discussion of the impact of different language features on their complexity. This section motivates the two main extensions brought by the authors to the DEC SRC Modula-3 compiler [1], a compilation server and fast code generator, and reviews related work.

Section 3 details the compilation server while section 4 describes the fast integrated code generator for Linux ELF [2]. Section 5 presents the results obtained with the enhanced compiler, and outlines the contribution of each extension as well as the sensitivity to different parameters. In the conclusion, the applicability of these results to other languages such as Java [3] and C++ [4] are discussed, and avenues for further development are examined.

2 Background

The different phases involved in recompiling a package, program or library, are detailed in this section. The work performed by typical compilers and by the DEC SRC Modula-3 compiler, possible enhancements, and related work are discussed at key steps.

The modification time of files comprising a package are checked to determine which ones were modified since the last compilation. These files always need to be recompiled. In an integrated development environment, this information may be provided by the editor, if all modifications are performed through it.

If any type checking, or data structure member offset computation, is performed at compile time, files have dependencies upon imported files containing declarations. This is not the case for languages such as Smalltalk [5] or LISP, which defer type checking to runtime, but applies to Java, C++

and Modula-3. When one of the declarations used by a file is changed, that file needs to be recompiled too.

The use of a text level macro preprocessor, for importing declarations from other files, makes such dependency analysis extremely difficult in C and C++. The traditional approach embodied by *makefiles* is to recompile a file whenever an included file was modified. The DEC SRC Modula-3 compiler remembers the fingerprint of each declaration used by a module, and recompiles the module only when any of the declarations used has a different fingerprint. This much finer grain dependency analysis, (at the level of individual type declaration instead of complete header file), explains in large part the smaller recompilation times typically associated with more structured languages, as compared to C/C++.

Computing the minimal set of files needing recompilation is the smart recompilation phase and has been studied in [6], [7], [8], and [9]. Any reduction in the number of files to recompile, due to a finer analysis, has a direct impact on the total recompilation time.

The set of modified files, and of files potentially affected by modifications in files on which they depend, is recompiled in the parsing and code generation phase. Compiling the individual files is often the most time consuming step. While minimizing the number of files to recompile is important, it is also possible to reduce the number of imported interfaces to parse, and to speedup the code generation phase.

The DEC SRC Modula-3 compiler already has a cache for imported interface files. Each imported interface is read at most once in each recompilation. A first extension, described in section 3, was to convert the compiler into a compilation server. This way, an imported file may be kept in the interface cache and need not be read and reparsed if it did not change between two compilations.

Koehler and Horspool [10] worked on a compilation server for the C language. Most of their effort was spent analyzing the pre-processor context, to determine if the imported file can be reused in different importers. It requires a validation scheme rather different than the one proposed here. Onodera proposed [11] a compilation server for a different language, COB, which has 2 kinds of interfaces, one similar to C and one similar to Modula-3.

The code generation time is a significant fraction of the total compilation time. A fast code generator for Linux ELF, based on an existing code generator for NT in SRC Modula-3, is a second extension described in section 4. Tanenbaum et al. [12], and Fraser et al. [13] have obtained interesting

results with fast but less flexible non optimizing backends.

In the prelink phase, a number of application wide informations may need to be computed, to be used by the run-time system. Non OO languages like C had little or none such information. In Modula-3, the initialization order of modules (based on the modules dependency graph), the run time type information (after resolving type equivalence), the coherence of opaque types revelations, and the structures for checking inheritance relationships in constant time, are computed during this prelink phase. In Java, initialization order is determined at runtime. C++ does not specify an initialization order and only recently started to offer run time type identification.

The final step, performed by the link editor, is assembling the object code of all the modules into the final executable. With dynamic linking, such as in Linux ELF [2], the amount of processing required is greatly reduced. All references internal to a module use position independent code and do not require further link editing. Moreover, links to libraries are resolved at execution time. Data symbols in libraries are resolved upon loading the executable but procedure references are resolved only when needed, as the execution proceeds.

3 Compilation Server

A compilation server reduces the recompilation time by maintaining some information across compilations, instead of reading and reparsing the corresponding files each time. Imported interfaces represent the bulk of the information required when compiling a file and often do not change from one compilation to another. Thus, the purpose of the compilation server is to maintain the interface cache across compilations.

Implementing a compilation server for C/C++ presents serious difficulties because of the preprocessor mechanism. For instance, the `#ifdef` in Figure 1 can lead to two different variables in the symbol table, depending on the value of `DEBUG`. Moreover, the compilation of an included `.h` file does not lead to an independent object file. Instead, the object code associated with it is part of the relocatable object files produced by the compilation of `.c` files that include the `.h` file.

In languages with explicit interfaces such as Modula-3, the content of an interface is not dependent on the importing file and can be reused for several importing files, even across compilations. Some languages such as Eiffel and

```

#ifdef DEBUG
int x
#else
int y
#endif

```

Figure 1: `#ifdef` example

Figure 2: Dependencies among imported Modula-3 interfaces

Java extract the interface from the program file. When the program file is recompiled, the interface is extracted. It could be stored in the interface cache of a compilation server in the same way.

Figure 2 shows the dependencies between interfaces A to E used by a program P. An arrow shows that a module or an interface imports another interface. This acyclic directed graph imposes a compilation order. The interfaces at the leaves are compiled first. Each interface is compiled separately, i.e. it has its own associated relocatable object file. However, an interface would normally need to be parsed again whenever it is imported. This is the costly part of the compilation avoided with the interface cache. The parsing result, the abstract syntax tree (*AST*), is stored in the interface cache.

Between compilations, some of the interfaces in the cache may become invalid. Indeed, if the associated source file has been modified or if a directly

or indirectly imported interface is invalid, the interface is declared invalid. In the last case, the fine grain dependency analysis is used to determine if any declaration actually used by the interface has changed. If not, the interface is still valid. Otherwise, the interface is removed from the cache and will need to be read and parsed again.

Thus, the validation algorithm is to recursively visit each imported interface in the graph to see if its associated source file has been modified or if imported declarations have changed. A time stamp is used to mark each valid interface as valid for this recompilation. When the same interface appears in the import graph of another file, the time stamp indicates that it has already been checked as valid. The existing implementation of DEC SRC Modula-3 did not have a validation phase since the interface cache was not kept across compilations. Any interface in the cache was necessarily parsed in the current compilation and therefore still valid.

A further optimization is added for interfaces imported from separate libraries (*packages*). Indeed, each *package* has an associated file containing the information used by the smart recompilation system. Any modification to an interface in a library, and subsequent recompilation, changes the modification time of the associated file. Thus, the modification time of library interfaces is checked only if the associated file has changed. Many libraries being seldom changed, this simple optimization avoids a large number of file modification time checks. The generic interfaces (the equivalent of the templates in C++) are not put in the cache because they don't have a corresponding AST. Their instantiations, however, are eligible to be cached.

Figures 3 and 4 show the general structure of the compiler before and after being transformed into a server. Libraries are represented as ovals and programs as rectangles. Import relationships are indicated by arrows. Programs executing other programs are shown with dashed lines.

Packages *m3front* and *m3back* are the frontend and the backend respectively. *M3linker* is the smart recompilation system. Package *m3* contains the main procedure of the compiler. *M3quake* is a simple interpreter that parses the m3makefiles and passes parameters to the compiler (*m3*). *M3build* initiates the *m3quake* interpreter in the appropriate directory, inserts the platform and package dependent definitions, and sends the m3makefile to *m3quake*. The connections to the two available code generators, and to the linker, were left out for simplicity.

The existing compiler involved several processes which were merged in a single executable program calling upon several libraries. Packages *m3* and

Figure 3: Structure of the SRC Modula-3 compiler

m3quake were converted to libraries. *M3build* acted as the remaining program and, instead of exiting after a recompilation, awaited further commands from clients using network objects [14], as shown in Figure 5.

Each client request consists in a package name and location, build options if any, and a network output stream to receive the error messages. The same compilation server can process requests for different packages. Simultaneous recompilation requests are serialized.

A small program, *m3client*, acts as a client that passes compilation requests to the server. It replaces the compilation command normally entered from the command line or through the editor menus.

There is currently no mechanism or strategy to remove interfaces from the cache (e.g. least recently used). This is not a problem for a few users working on a few packages. However, if the compilation server executes for weeks and new packages are constantly being added, the memory growth is likely to become a problem. Deciding on an efficient strategy may require some study but would be a minor implementation effort. The problem of multi-user access control has not been addressed either. Sharing a compilation server would bring interesting benefits only in very specific environments.

An alternative to maintaining the parsed interfaces in memory in a server process across compilations, is to store on disk pre-parsed versions of the interfaces. This would be faster than having no compilation server, if writing these pre-parsed interfaces is much quicker than the time saved by not having to re-parse the interfaces. However, this is slower than keeping the parsed interfaces already in memory, provided that enough memory is available.

Figure 4: Structure of the modified SRC Modula-3 compiler

4 Fast Code Generation

Portable, retargetable, optimizing compilers such as gcc are built in several layers and construct abstract syntax trees, an intermediate language representation, and an assembly language file at different stages during the compilation. Furthermore, the interface between the Modula-3 frontend, written in Modula-3, and the gcc based backend introduces another intermediate representation.

While the gcc based backend is retained to benefit from its optimizing capabilities and wide range of supported platforms, an integrated code generator may be used on some platforms for faster compilation during the edit compile debug cycle. The code generator is fed by the frontend with simple virtual machine instructions and generates object code directly. It cannot perform sophisticated optimizations or target multiple platforms.

An existing code generator for NT under Intel 386 was used as a base. It was modified to support Linux ELF object files [2], and to produce position independent code and debugging information. Position independent code allows efficient dynamic linking, another important ingredient for fast recompilation. Debugging information generation increases slightly the code generation time but is almost essential for adequately supporting the edit compile debug cycle.

Figure 6 *a)* shows a simple Modula-3 procedure returning the sum of two

```

INTERFACE M3Server;
IMPORT NetObj, Thread, Wr, Pathname, TextList;
EXCEPTION
  Error (TEXT);
TYPE
  T = NetObj.T OBJECT METHODS
    compile(init_dir:Pathname.T;options:TextList.T;writer:Wr.T)
      RAISES NetObj.Error, Thread.Alerted, Error;
    END;
END M3Server.

```

Figure 5: Network object interface to the compilation server

values received as arguments. In *b*), the sequence of methods calls issued by the Modula-3 frontend, and implemented by the code generator object, is illustrated. The methods supported by the code generation object are sometimes called the intermediate language. The arguments for the methods were omitted in the example. In *c*), the machine code produced by the backend is presented in the AT&T assembly language format for Intel 386 Architecture.

At the beginning of a procedure, the method *begin_procedure* is called by the frontend, and the 6 first machine instructions are generated. This saves on the stack and initializes the registers used for setting up a new frame according to the calling convention. Figure 7 shows the structure of the stack frame constructed with these instructions. The *ebp* register (base register) is used to reference other values in the stack frame by specifying a 4 byte offset in an indexed address mode. The stack frame also includes the arguments to the procedure, the return address of the calling procedure, the value of *ebp* for the previous stack frame, local variables, and some saved register values.

Thereafter, the machine instructions corresponding to the body of the Modula-3 procedure are generated. The *load* method is called twice by the frontend, once for each operand. No machine code is generated for this. Instead, the operands are pushed on the operand stack in the data structures maintained by the code generator. The call of the method *add* by the frontend generates the code for adding the operands previously pushed on the stack. On the i386, at least one operand of *add* must be in a register. Thus,

```

PROCEDURE Add(i, j:  INTEGER): INTEGER =
  BEGIN
    RETURN i + j;
  END Add;

```

(a)

begin_procedure(...)		pushl %ebp
		movl %esp,%ebp
		pushl %ebx
		pushl %esi
load(...)		pushl %edi
load(...)		
add(...)		movl 0x8(%ebp),%edx
		addl 0xc(%ebp),%edx
exit_proc(...)		movl %edx,%eax
end_procedure(...)		popl %edi
		popl %esi
		popl %ebx
		leave
		ret

(b)

(c)

Figure 6: Compilation of a simple procedure.

one variable must be moved from its position in the stack frame in memory to a register (here *edx*). The other operand can be addressed directly in memory by instruction *add*. The result of the addition must be returned to the calling procedure in register *eax*, as specified in the calling convention. Thus, the value in *edx* is moved to *eax* when method *exit_procedure* is called by the frontend. The call to method *end_procedure* generates the code required to remove the stack frame and restore affected registers.

Several optimizations to the generated code would be possible. For example, the use of register *edx* could be avoided by using *eax* instead. This would obviate the need to transfer the return value to *eax* in the end. Registers *ebx*, *esi* and *edi* were needlessly saved and restored on the stack even if they were not used during the body of the procedure. Even though the fast code generator does not perform such optimizations, the generated code is still more efficient than the naive code produced by gcc without optimization, as

Figure 7: Stack frame

seen in section 5.

The code generator structure is designed around four major objects, as shown in Figure 8. The main object is *M3x86* which implements code generation for procedure calls and returns, and produces the global variables section. It also coordinates the code generation performed by the other objects. *Stackx86* implements the operand stack, performs the register allocation and generates the code to move operands between the stack and the registers. Detailed machine instructions layouts, including addressing modes, are obtained through the *Codex86* object. Everything is formatted into an ELF binary file, with debugging information, by *M3ObjFile*. The relationships between these objects are represented by arrows in Figure 8.

5 Results

The test set used for the performance evaluation is described in Table 1. It contains programs and libraries of different sizes, and importing different types of libraries. Large graphical applications such as webscape, postcard, and ps2html tend to use large libraries, and involve numerous imported interfaces. Webvbt is one of the libraries used by webscape, and columns is a smaller graphical application. Netobjd is a small program involving network objects, and m3browser is a module/type browser with a web server interface. M3tohtml is a small program converting Modula-3 modules to html, and m3front is a library implementing the Modula-3 compiler frontend.

For each package are shown the source code size, number of lines, number of non blank lines, number of directly and indirectly imported interfaces, and

Figure 8: Structure of the code generator.

the memory consumed by the interface cache to represent the AST. All tests were performed on a 75MHz Intel Pentium with 32MB of main memory and running Linux 2.0. All times are in elapsed seconds on a single user machine, and thus account for input/output delays.

The performance of both the integrated backend and the compilation server were evaluated and compared to the original DEC SRC Modula-3 compiler version 3.6. The compilation times for the original compiler are in Table 2.

Detailed measures were obtained for the various compilation phases using the compiler built-in timers. Column $M3 \Rightarrow I.L.$ is the time required to translate Modula-3 code into intermediate language, which is performed by the frontend. $I.L. \Rightarrow ass.$ is the time needed by the gcc based backend (m3cgc1) to convert the intermediate language into assembly, and $ass. \Rightarrow reloc.$ is the time taken by the assembler to produce a relocatable binary file.

Table 3 presents the results for the compiler with the integrated backend instead of the gcc based backend. The fast code generator goes directly from the code generating method calls to the relocatable binary file, as indicated by $M3 \Rightarrow reloc.$ Since the code generation is performed at the same time as parsing, the time required for each phase is not available separately.

Table 3: Compilation with the integrated backend

The compilation time reduction is significant for all packages. When the compilation time is larger than 20 seconds with the gcc based backend, the total compilation time may be cut in half with the integrated backend. Other tests [15] demonstrate that the production of position independent code does not significantly affect the compilation time. However, the generation of debugging information increases the total compilation time by 10-30%.

To evaluate the quality of the generated code, a program was compiled with the gcc based backend without optimization and with full optimization (-O2), and with the fast code generator. The execution time for the version compiled with the fast code generator was 6% faster than without optimization and 9% slower than with optimization. The memory footprint of the program compiled with the fast code generator is 18% smaller than without optimization and 14% larger than with optimization.

These results are consistent with those reported by Tanenbaum and al. [12], where they obtained a speedup between 2 and 3 by using a simplified backend. Their backend however still retained the ability to interface to different frontends and targets.

The compilation server was evaluated both under a full recompilation and in a typical situation where only a few files were modified. For the first case, the executable and all object files were removed before recompiling. This is

package compiled	Time (in seconds)						
	smart recomp.	M3 $\Rightarrow$ I.L.	I.L. $\Rightarrow$ ass.	ass. $\Rightarrow$ reloc.	linking	other	total
columns	0.63	1.96	9.04	4.45	0.86	0.26	17.20

Table 4: Full recompilation of the packages with AST's in the cache

shown in Table 4.

The savings brought by maintaining the interface cache across two compilations are smaller than originally anticipated. Only small gains are obtained for the small packages. Since the SRC Modula-3 compiler already contains an interface cache, the time to parse the interfaces is relatively small as compared to the code generation time, and a small fraction of the time is saved by caching the interfaces across compilations.

More disturbing is the slight degradation obtained for some of the larger packages. Removing the network objects communication between the client and server did not change the results. The explanation lies in the increased memory footprint of the compilation server. With 32 MB, there is some competition for physical memory between buffered files (e.g. libraries, object files and the generated executable), and executing programs (e.g. the compiler and linker). Indeed, when the same tests were repeated on a computer with twice as much physical memory, a slight improvement was measured instead of a degradation.

In a full recompilation, the existing interface cache brings most of the benefits, and the code generation phase largely dominates because all modules need to be recompiled. Therefore, the savings brought by the server are minor as compared to the total compilation time and may even turn into

compiler used	Time (in seconds)						
	smart recomp.	M3 $\Rightarrow$ I.L.	I.L. $\Rightarrow$ ass.	ass. $\Rightarrow$ reloc.	linking	other	total
standard with m3cgc1	0.73	0.97	2.73	0.86	0.42	0.22	5.93

server with integrated	0.64	1.36			0.42	0.20	2.62

Table 5: Recompilation of postcard after modifications to 2 files

a degradation if memory is short. The picture improves however when the compilation server is combined with the fast code generator. Indeed, the 2.46s reduction for columns represents 12.5% of 19.66s but amount to 27.1% of 9.08s. These savings only involve the smart recompilation and frontend parsing phase, and are independent of the code generation time.

The tests presented in Tables 5 and 6 are more typical of the edit compile debug cycle. They consist in recompiling a large graphical application, postcard, after 2 files, and 4 files, are modified. Four different cases are covered: existing compiler and code generator, fast code generator, compilation server, compilation server with fast code generator. For these tests, the computer used had the same characteristics except a Pentium Pro 180MHz processor and 64MB of RAM.

These tests clearly demonstrate that the compilation server and fast code generator contribute independently to the recompilation time reduction. Their combined effect in that case amounts to a reduction from 9.77s to 3.22s. This is especially impressive considering that the Modula-3 compiler is already much more efficient than most C/C++ compilers, because of the interface cache and fine grain dependency analysis allowed by the structured interface mechanism.

compiler used	Time (in seconds)

6 Conclusion

A fast recompilation system for a modular, compiled, object oriented language was presented. It benefits from the existing interface cache and fine grain dependency analysis, and was extended with a persistent interface cache, fast code generator, and Linux ELF dynamic libraries support. The resulting recompilation time reduction is impressive. For a large graphical application, recompiling after a few files were modified took 3.22s instead of 9.77s.

In the coming years, faster processors, larger main memory and more complex programs may be expected. The average size of each file, and the number of files modified between compilations are not expected to change significantly however. The net effect would be a gradual reduction of the file parsing and code generation time, which currently dominates the recompilation time at 2.05s out of 3.22s. The smart recompilation and linking time accounts for much of the remaining time (.92s out of 1.17s). These may be adversely affected by the increasing programs complexity and eventually dominate the recompilation time.

Increases in programs complexity are likely to change more the number of libraries imported by each program rather than the size of each program file or library. The smart recompilation system could accordingly be further optimized in several ways. More information about each imported library

could be cached, as applications importing more libraries have much larger times for the smart recompilation phase. A tighter integration between the program editor and the compilation server could allow the smart recompilation to perform most of its work incrementally. When a file is opened and modified, the compiler could pre-compute which files are affected, and need to be recompiled or dependency checked. When a file is saved, the recompilation of that file and affected files may proceed. Thus, when the last file is saved, only that last file, and the files affected, would need recompilation.

The final recompilation steps, prelinking and linking, involve the complete program and may therefore become the dominant step as program complexity increases. Interestingly, the Linux ELF linker is surprisingly efficient for dynamically linked libraries. Only a small fraction of each library needs to be read by the linker. Yet, because of the lazy procedure linking algorithm used in ELF, the program startup penalty imposed by dynamic linking is small. As may be seen from the results, the linking time is mostly affected by the package size rather than by the number of imported libraries.

Linking is an I/O intensive process, and the availability of free RAM for the I/O buffer cache strongly impacts the elapsed time. This was apparent for large programs where the compilation server actually degraded the performance because of the competition for memory. Assuming sufficient physical memory, it may be possible to reduce the linking time by dynamically loading each object file as it is being recompiled. This would remove the linking step which reads all object files from disk, merges the files into an executable, and writes the executable to disk, before loading the executable.

The prelinking step, listed as *other*, currently uses a small fraction of the overall recompilation time. It checks the coherency of opaque types revelations, determines the modules initialization order, and generates the run time type identification data structures. The processing time is proportional to the total number of modules in the final program. With increasing program complexities, this may in the long term become an important factor.

In C++, run time type identification is a recent addition and is likely to bring different problems. Indeed, a declaration appearing in a *.h* file may be included and compiled several times. The prelinker must ideally remove duplicate virtual methods tables and run time type information. The Java language does not specify a static initialization order nor does it have opaque types to check. The prelinker step is thus mostly avoided. However, since a class must be initialized at its first active use, many tests must be inserted at run time to initialize classes when they are used, if it is the first time. Thus,

the savings in the prelink phase are offset by the run time overhead.

The fast code generator is now part of the freely redistributable Polytechnique Montreal Modula-3 distribution, originally found at <http://m3.polymtl.ca/m3/pkg> but now hosted at <http://www.elegosoft.com/pm3/>, and received enthusiastic feedback from users around the world. The compilation server is available separately at <http://www.professeurs.polymtl.ca/michel.dagenais/pkg/m3server.tar.gz>.

Acknowledgments

The financial support of the National Sciences and Engineering Research Council of Canada, as a scholarship to the first author, while he was a master's student at Ecole Polytechnique de Montreal, and an operating grant to the second author, is gratefully acknowledged. This work would not have been possible without the excellent environment provided by the DEC SRC Modula-3 compiler. Bill Kalsow, Allan Heydon, and Greg Nelson contributed to this project through numerous technical discussions.
